2 ABSTRACT

Cortical pyramidal neurons have a complex dendritic anatomy, whose function is an active research field. In particular, the segregation between its soma and the apical dendritic tree is believed to play an active role in processing feed-forward sensory information and top-down or feedback signals. In this work, we use a simple two-compartment model accounting for the nonlinear interactions between basal and apical input streams and show that standard unsupervised Hebbian learning rules in the basal compartment allow the neuron to align the feed-forward basal input with the top-down target signal received by the apical compartment. We show that this learning process, termed coincidence detection, is robust against strong distractions in the basal input space and demonstrate its effectiveness in a linear classification task.

Keywords: Dendrites, Pyramidal Neuron, Plasticity, Coincidence Detection, Supervised Learning

1 INTRODUCTION

In recent years, a growing body of research has addressed the functional implications of the distinct physiology and anatomy of cortical pyramidal neurons (Spruston, 2008; Hay et al., 2011; Ramaswamy and Markram, 2015). In particular, on the theoretical side, we saw a paradigm shift from treating neurons as point-like electrical structures towards embracing the entire dendritic structure (Larkum et al., 2009; Poirazi, 2009; Shai et al., 2015a). This was mostly due to the fact that experimental work uncovered dynamical properties of pyramidal neuronal cells that simply could not be accounted for by point models (Spruston et al., 1995; Häusser et al., 2000).

An important finding is that the apical dendritic tree of cortical pyramidal neurons can act as a separate nonlinear synaptic integration zone (Spruston, 2008; Branco and Häusser, 2011). Under certain conditions, a dendritic Ca^{2+} spike can be elicited that propagates towards the soma, causing rapid, bursting spiking activity. One of the cases in which dendritic spiking can occur was termed ‘backpropagation-activated Ca^{2+} spike firing’ (‘BAC firing’): A single somatic spike can backpropagate towards the apical spike initiation zone, in turn significantly facilitating the initiation of a dendritic spike (Stuart and Häusser, 2001; Spruston, 2008; Larkum, 2013). This reciprocal coupling is believed to act as a form of coincidence detection: If apical and basal synaptic input co-occurs, the neuron can respond with a rapid burst of spiking activity. The firing rate of these temporal bursts exceeds the firing rate that is maximally achievable under basal

30 synaptic input alone, therefore representing a form of temporal coincidence detection between apical and
31 basal input.

32 Naturally, these mechanisms also affect plasticity and thus learning within the cortex (Sjöström and
33 Häusser, 2006; Ebner et al., 2019). While the interplay between basal and apical stimulation and its effect
34 on synaptic efficacies is subject to ongoing research, there is evidence that BAC-firing tends to shift
35 plasticity towards long-term potentiation (LTP) (Letzkus et al., 2006). Thus, coincidence between basal
36 and apical input appears to also gate synaptic plasticity.

37 In a supervised learning scheme, where the top down input arriving at the apical compartment acts as the
38 teaching signal, the most straight-forward learning rule for the basal synaptic weights would be derived
39 from an appropriate loss function, such as a mean square error, based on the difference between basal and
40 apical input, i.e. $I_p - I_d$, where indices p and d denote ‘proximal’ and ‘distal’, in equivalence to basal and
41 apical. Theoretical studies have investigated possible learning mechanisms that could utilize an intracellular
42 error signal (Urbanczik and Senn, 2014; Schiess et al., 2016; Guergiev et al., 2017). However, a clear
43 experimental evidence for a physical quantity encoding such an error is—to our knowledge—yet to be
44 found. On the other hand, Hebbian-type plasticity is extensively documented in experiments (Gustafsson
45 et al., 1987; Debanne et al., 1994; Markram et al., 1997; Bi and Poo, 1998). Therefore, our work is based
46 on the question whether the non-linear interactions between basal and apical synaptic input could, when
47 combined with a Hebbian plasticity rule, allow a neuron to learn to reproduce an apical teaching signal in
48 its proximal input.

49 We investigate coincidence learning by combining a phenomenological model that generates the output
50 firing rate as a function of two streams of synaptic input (subsuming basal and apical inputs) with classical
51 Hebbian, as well as BCM-like plasticity rules on basal synapses. In particular we hypothesized that this
52 combination of neural activation and plasticity rules would lead to an increased correlation between basal
53 and apical inputs. Furthermore, the temporal alignment observed in our study could potentially facilitate
54 apical inputs to act as top-down teaching signals, without the need for an explicit error-driven learning
55 rule. Thus, we also test our model in a simple linear supervised classification task and compare it with the
56 performance of a simple point neuron equipped with similar plasticity rules.

2 MODEL

57 2.1 Compartmental Neuron

The neuron model used throughout this study is a discrete-time rate encoding model that contains two separate input variables, subsuming the total synaptic input current injected arriving at the basal (proximal) and apical (distal) dendritic structure of a pyramidal neuron, respectively. The model is a slightly simplified version of a phenomenological model proposed by Shai et al. (2015b). Denoting the input currents I_p (proximal) and I_d (distal), the model is written as

$$y(t) = \alpha \sigma(I_p(t) - \theta_{p0}) [1 - \sigma(I_d(t) - \theta_d)] + \sigma(I_d(t) - \theta_d) \sigma(I_p(t) - \theta_{p1}) \quad (1)$$

$$\sigma(x) \equiv \frac{1}{1 + \exp(-4x)}. \quad (2)$$

58 Here, $\theta_{p0} > \theta_{p1}$ and θ_d are threshold variables with respect to proximal and distal inputs. Overall, equation
59 (1) describes two distinct regions of neural activation in the (I_p, I_d) -space which differ in their maximal
60 firing rates, which are set to 1 and α , where $0 < \alpha < 1$. A plot of (1) is shown in Fig. 1.

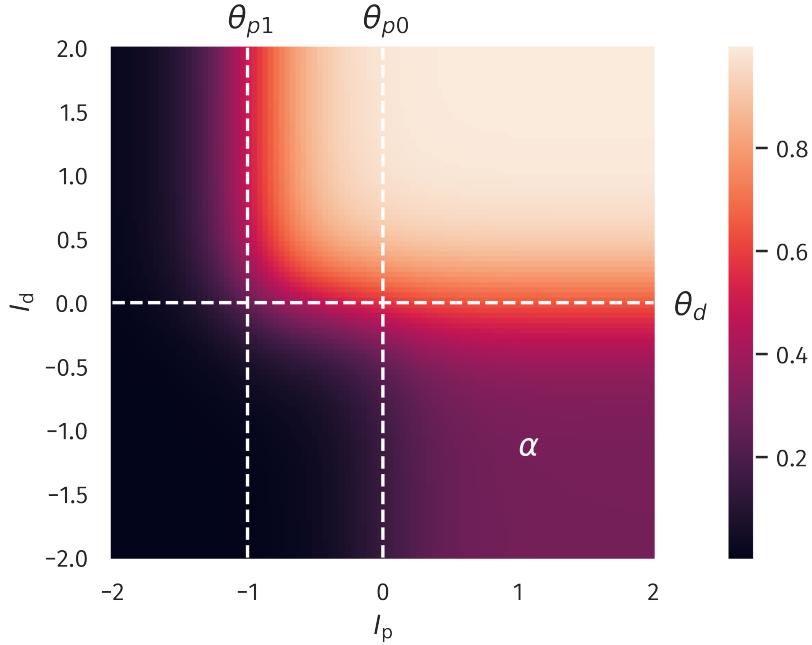

Figure 1. Two-compartment rate model. The firing rate as a function of proximal and distal inputs I_p and I_d , see (1). The thresholds θ_{p0} , θ_{p1} and θ_d define two regions of neural activity, with a maximal firing rate of unity an a plateau at $\alpha = 0.3$.

When both input currents I_d and I_p are large, viz larger than the thresholds θ_d and θ_{p1} , the second term in (1) dominates, which leads to $y \approx 1$. An intermediate activity plateau, of strength α emerges in addition when $I_p > \theta_{p0}$ and $I_d < \theta_d$. As such, the compartment model (1) is able to distinguish neurons with a normal activity level, here encoded by $\alpha = 0.3$, and strongly bursting neurons, where the maximal firing rate is unity. The intermediate plateau allows neurons to process the proximal inputs I_p even in the absence of distal stimulation. The distal current I_d acts therefore as an additional modulator.

In our numerical experiments we compare the compartment model with a classical point neuron, as given by

$$y(t) = \sigma(I_p(t) + I_d(t) - \theta) . \quad (3)$$

The apical input I_d is generated ‘as is’, meaning, it is not dynamically calculated as a superposition of multiple presynaptic inputs. For concreteness, we used

$$I_d(t) = n_d(t)x_d(t) - b_d(t) , \quad (4)$$

where $n_d(t)$ is a scaling factor, $x_d(t)$ a pre-generated discrete time sequence and $b_d(t)$ a bias. Note that n_d and b_d are time dependent since they are subject to adaptation processes, which will be described in the next section. Similarly, the proximal input $I_p(t)$ is given by

$$I_p(t) = n_p(t) \sum_{i=1}^N x_{p,i}(t)w_i(t) - b_p(t) , \quad (5)$$

where N is the number of presynaptic afferents, $x_{p,i}(t)$ the corresponding sequences, $w_i(t)$ the synaptic efficacies and $n_p(t)$ and $b_p(t)$ the (time dependent) scaling and bias. Tyical values for the parameters used throughout this study are presented in Table 1.

77 **2.2 Homeostatic Parameter Regulation**

The bias variables entering the definitions (4) and (5) of the distal proximal current, I_d and I_p , are assumed to adapt according to

$$b_p(t+1) = b_p(t) + \mu_b [I_p(t) - I_p^t] \quad (6)$$

$$b_d(t+1) = b_d(t) + \mu_b [I_d(t) - I_d^t], \quad (7)$$

78 where $I_p^t = 0$ and, $I_d^t = 0$ are preset targets and $1/\mu_b = 10^3$ the timescale for the adaption process. Over
79 time, both the distal and the proximal currents, I_d and I_p , average out.

Adaptation rules for the bias entering a transfer function, such as (7) and (6), have the task to regulate overall activity levels. The overall magnitude of the synaptic weights, which are determined by synaptic rescaling factors, here n_d and n_p , as defined in (4) and (5), will regulate in contrast the variance of the neural activity, and not the average level (Schubert and Gros, 2021). In this spirit we consider

$$n_d(t+1) = n_d(t) + \mu_n \left[V_d^t - (I_d(t) - \tilde{I}_d(t))^2 \right] \quad (8)$$

$$n_p(t+1) = n_p(t) + \mu_n \left[V_p^t - (I_p(t) - \tilde{I}_p(t))^2 \right] \quad (9)$$

$$\tilde{I}_d(t+1) = (1 - \mu_{av})\tilde{I}_d(t) + \mu_{av}I_d(t) \quad (10)$$

$$\tilde{I}_p(t+1) = (1 - \mu_{av})\tilde{I}_p(t) + \mu_{av}I_p(t) \quad (11)$$

80 Here, V_p^t and V_d^t define targets for the temporal averaged variances of I_p and I_d . The dynamic variables \tilde{I}_p
81 and \tilde{I}_d are simply low-pass filtered running averages of I_p and I_d . Overall, the framework specified here
82 allows the neuron to be fully flexible, as long as the activity level and its variance fluctuate around preset
83 target values (Schubert and Gros, 2021). A list of the parameter values used throughout this investigation is
84 also given in Table 1. Our choices of target means and variances are based on the assumption that neural
85 input should be tuned towards a certain working regime of the neural transfer function. In the case of the
86 presented model, this means that both proximal and distal input cover an area where the nonlinearities of
87 the transfer function are reflected without oversaturation.

Table 1. Model parameters, as defined in sections 2.1 and 2.3.

θ_{p0}	0	V_d^t	0.25
θ_{p1}	-1	μ_b	10^{-3}
θ_d	0	μ_n	10^{-4}
α	0.3	μ_{av}	$5 \cdot 10^{-3}$
μ_w	$5 \cdot 10^{-5}$	I_p^t	0
ϵ	0.1	I_d^t	0
V_p^t	0.25		

88 **2.3 Synaptic Plasticity**

The standard Hebbian plasticity rule for the proximal synaptic weights is given by

$$w_i(t+1) = w_i(t) + \mu_w [(x_{p,i}(t) - \tilde{x}_{p,i}(t)) (y(t) - \tilde{y}) - \epsilon w_i(t)] \quad (12)$$

$$\tilde{x}_{p,i}(t+1) = (1 - \mu_{av})\tilde{x}_{p,i}(t) + \mu_{av}x_{p,i}(t) \quad (13)$$

$$\tilde{y}(t+1) = (1 - \mu_{av})\tilde{y}(t) + \mu_{av}y(t) \quad (14)$$

89 The trailing time averages $\tilde{x}_{p,i}$ and \tilde{y} , respectively of the presynaptic basal activites, $x_{p,i}$, and of the neural
90 firing rate y , enter the Hebbian learing rule (12) as reference levels. Pre- and post-synaptic neurons are
91 considered to be active/inactive when being above/below the respective trailing averages. The timescale
92 of the averaging, $1/\mu_{av}$, is typically over 200 time steps, see Table 1. Since classical Hebbian learning
93 does not keep weights bounded, we use an additional proportional decay term ϵw_i which prevents runaway
94 growth using $\epsilon = 0.1$. With $1/\mu_w = 2 \cdot 10^4$, learning is assumed to be considerably slower, as usual for
95 statistical update rules. For comparative reasons, the point neuron model (3) is equipped with the same
96 plasticity rule for the proximal weights as (12).

97 Apart from classical Hebbian learning, we also considered a BCM-like learning rule for the basal weights
98 (Bienenstock et al., 1982; Intrator and Cooper, 1992). The form of the BCM-rule used here reads

$$w_i(t+1) = w_i(t) + \mu_w [y(y - \theta_M) x_i - \epsilon w_i], \quad (15)$$

99 where θ_M is a threshold defining a transition from long-term potentiation (LTP) to long-term depression
100 (LTD) and, again, ϵ is a decay term on the weights preventing unbounded growth. In the variant introduced
101 by Law and Cooper (1994), the sliding threshold is simply the temporal average of the squared neural
102 activity, $\theta_M = \langle y^2 \rangle$. In practice, this would be calculated as a running average, thereby preventing the
103 weights from growing indefinitely.

104 However, for our compartment model, we chose to explicitly set the threshold to be the mean value
105 between the high- and low-activity regime in our compartment model, i.e. $\theta_M = (1 + \alpha)/2$. By doing
106 so, LTP is preferably induced if both basal and apical input are present at the same time. Obviously, for
107 the point model, the reasoning behind our choice of θ_M did not apply. Still, to provide some level of
108 comparability, we also ran simulations with a point model where the sliding threshold was calculated as a
109 running average of y^2 .

3 RESULTS

110 **3.1 Unsupervised Alignment between Basal and Apical Inputs**

111 As a first test, we quantify the neuron's ability to align its basal input to the apical teaching signal. This can
112 be done using the pearson correlation coefficient $\rho[I_p, I_d]$ between the basal and apical input currents. We
113 determined $\rho[I_p, I_d]$ after the simulation, which involves all plasticity mechanisms, both for the synaptic
114 weights and for the intrinsic parameters. The input sequences $x_{p,i}(t)$ is randomly drawn from a uniform
115 distribution, in $[0, 1]$, which is done independently for each $i \in [1, N]$.

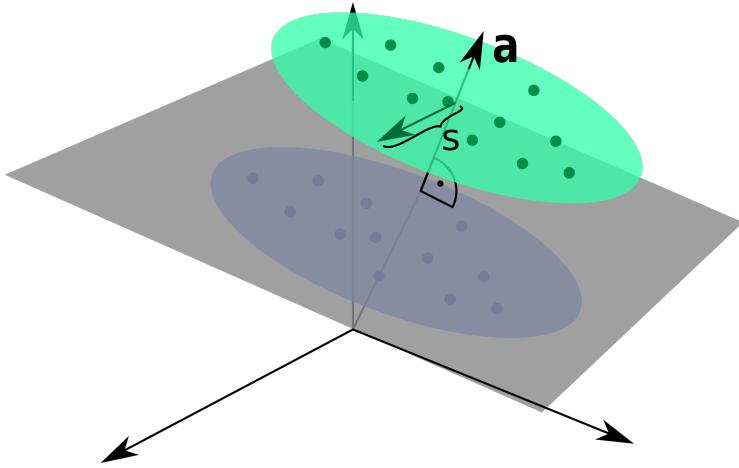

Figure 2. Input Space for the Linear Classification Task. Two clusters of presynaptic basal activities were generated from multivariate Gaussian distributions. Here, s denotes the standard deviation orthogonal to the normal vector a of the classification hyperplane, as defined by (16).

For the distal current $I_d(t)$ to be fully ‘reconstructable’ by the basal input, $x_d(t)$ has to be a linear combination

$$x_d(t) = \sum_{i=1}^N a_i x_{p,i}(t) \quad (16)$$

116 of the $x_{p,i}(t)$, where the a_i are the components of a random vector a of unit length.

117 Given that we use with (12) a Hebbian learning scheme, one can expect that the direction and the
118 magnitude of the principal components of the basal input may affect the outcome of the simulation
119 significantly: A large variance in the basal input orthogonal to the ‘reconstruction vector’ a is a distraction
120 for the plasticity. The observed temporal alignment between I_p and I_d should hence suffer when such a
121 distraction is present.

122 In order to test the effects of distracting directions, we applied a transformation to the input sequences
123 $x_{p,i}(t)$. For the transformation, two parameters are used, a scaling factor s and the dimension N_{dist} of the
124 distracting subspace within the basal input space. The N_{dist} randomly generated basis vectors are orthogonal
125 to the superposition vector a , as defined by (16), and to each others. Within this N_{dist} -dimensional subspace,
126 the input sequences $x_{p,i}(t)$ are rescaled subsequently by the factor s . After the learning phase, a second set
127 of input sequences $x_{p,i}(t)$ and $x_d(t)$ is generated for testing purposes, using the identical protocol, and the
128 cross correlation $\rho[I_p, I_d]$ evaluated. During the testing phase plasticity is turned off.

129 The overall aim of our portocal is to evaluate the degree $\rho[I_p, I_d]$ to which the proximal current I_p aligns
130 in the temporal domain to the distal input I_d . We recall that this is a highly non-trivial question, given that
131 the proximal synaptic weights are adapted via Hebbian plasticity, see (12). The error $(I_p - I_d)^2$ does not
132 enter the adaption rules employed. Results are presented in Fig. 3 as a function of the distraction parameters
133 s and $N_{\text{dist}} \in [0, N - 1]$. The total number of basal inputs is $N = 100$.

134 For a comparison, in Fig. 3 data for both the compartment model and for a point neuron are presented (as
135 defined respectively by (1) and (3)), as well as results for both classical Hebbian and BCM learning rules.
136 A decorrelation transition as a function of the distraction scaling parameter s is observed for both models
137 and plasticity rules. In terms of the learning rules, only marginal differences are present. However, the

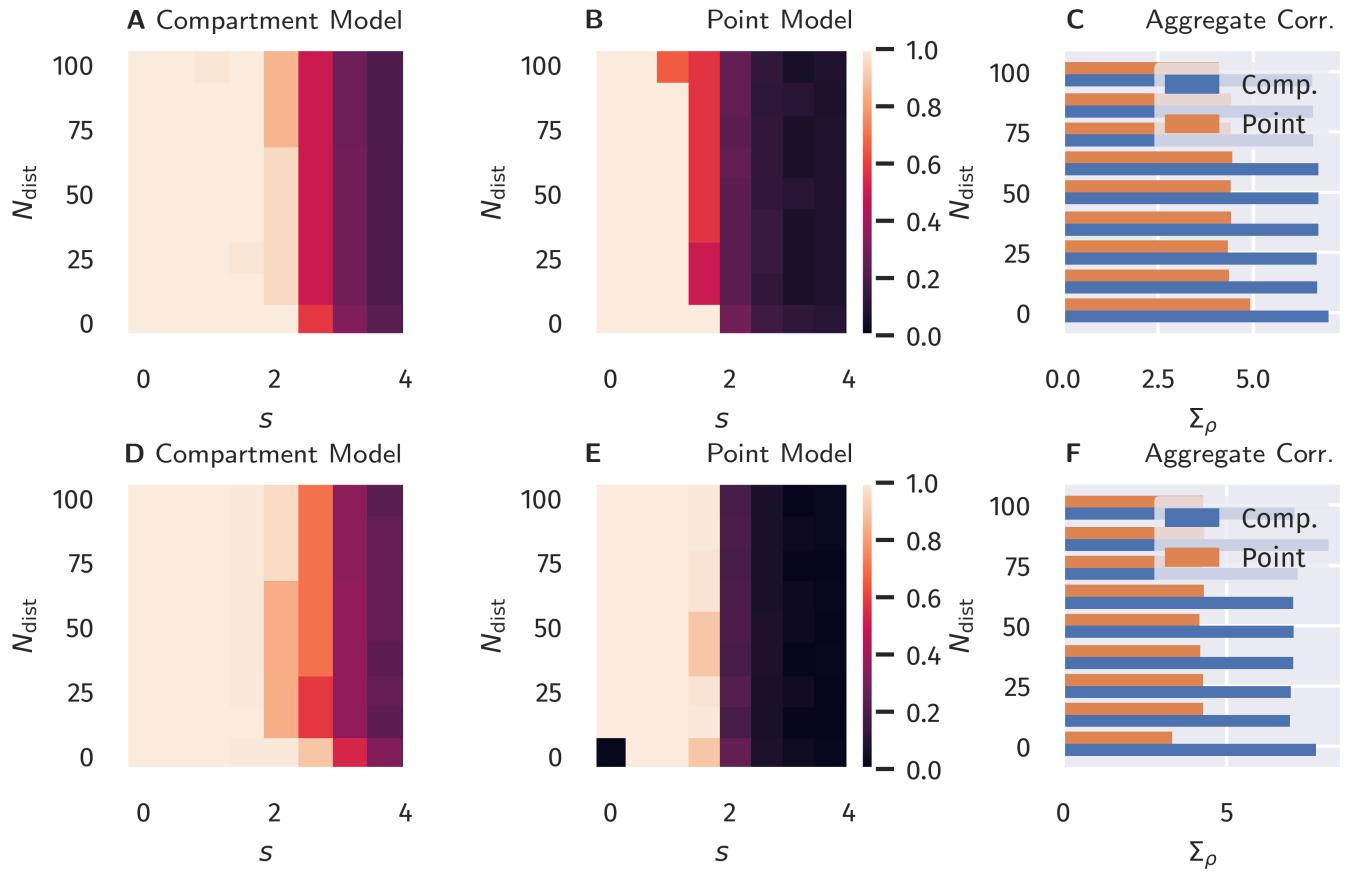

Figure 3. Unsupervised Alignment between Basal and Apical Input. Color encoded is the Pearson correlation $\rho[I_p, I_d]$ between the proximal and distal input currents, I_p and I_d . A–C: Classical Hebbian plasticity, as defined by (12). D–F: BCM rule, see (15). Data for a range $N_{\text{dist}} \in [0, N - 1]$ of the orthogonal distraction directions, and scaling factors s , as defined in Fig. 2. The overall number of basal inputs is $N = 100$. In the bar plot on the right the sum Σ_{acc} over $s = 0, 0.5, 1.0 \dots$ of the results is shown as a function of N_{dist} . Blue bars represent the compartment model, orange the point model.

138 compartment model is able to handle a significantly stronger distraction as compared to the point model.
 139 These findings support the hypothesis examined here, namely that nonlinear interactions between basal and
 140 apical input improve learning guided by top-down signals.

141 3.2 Supervised Learning in a Linear Classification Task

142 Next, we investigated if the observed differences would also improve the performance in an actual
 143 supervised learning task. For this purpose, we constructed presynaptic basal input $x_p(t)$ as illustrated in
 144 Fig. 2. Written in vector form, each sample from the basal input is generated from,

$$\mathbf{x}_p(t) = \mathbf{b} + \mathbf{a}[c(t) + \sigma_a \zeta_a(t)] + s \cdot \sum_{i=1}^{N_{\text{dist}}} \zeta_{\text{dist},i}(t) \mathbf{v}_{\text{dist},i}, \quad (17)$$

145 where \mathbf{b} is a random vector drawn uniformly from $(0, 1)^N$, \mathbf{a} is random unit vector as introduced in
 146 Section 3.1, $c(t)$ is a binary variable drawn from $\{-0.5, 0.5\}$ with equal probability and $\zeta_a(t)$ and the
 147 $\zeta_{\text{dist},i}(t)$ are independent random Gaussian variables with zero mean and unit variance. Hence, σ_a simply
 148 denotes the standard deviation of each Gaussian cluster along the direction of the normal vector \mathbf{a} and

149 was set to $\sigma_a = 0.25$. Finally, the set of $\mathbf{v}_{\text{dist},i}$ forms a randomly generated orthogonal basis of N_{dist}
 150 unit vectors which are—as in Section 3.1—also orthogonal to \mathbf{a} . The free parameter s parameterizes the
 151 standard deviation along this subspace orthogonal to \mathbf{a} . As indicated by the time dependence, the Gaussian
 152 and binary random variables are drawn for each time step. The vectors \mathbf{b} , \mathbf{a} , and $\mathbf{v}_{\text{dist},i}$ are generated once
 153 before the beginning of a simulation run.

For the classification task, we use two output neurons, indexed 0 and 1, receiving the same basal presynaptic input, with the respective top-down inputs $x_{d,0}$ and $x_{d,1}$ encoding the desired linear classification in a one-hot scheme,

$$x_{d,0}(t) = 1 - \Theta((\mathbf{x}_p(t) - \mathbf{b})^T \mathbf{a}) \quad (18)$$

$$x_{d,1}(t) = \Theta((\mathbf{x}_p(t) - \mathbf{b})^T \mathbf{a}), \quad (19)$$

154 where $\Theta(x)$ is the Heaviside step function.

155 As in the previous experiment, we ran a full simulation until all dynamic variables reached a stationary
 156 state. After this, a test run without plasticity and with the apical input turned off was used to evaluate the
 157 classification performance. For each sample, the index of the neuron with the highest activity was used as
 158 the predicted class. Accuracy was then calculated as the fraction of correctly classified samples.

159 The resulting accuracy as a function of N_{dist} and s is shown in Fig. 4, again for all four combinations of
 160 neuron models and learning rules.

161 For classical Hebbian plasticity, the differences between compartmental and point neuron are small.
 162 Interestingly, the compartment model performs measurably better in the case of the BCM rule (15), in
 163 particular when the overall accuracies for the tested parameter range are compared, see Fig. 4D. This
 164 indicates that the compartmental neuron makes better use, during learning, of the three distinct activity
 165 plateaus at 0, α and 1, when the BCM rule is at work. Compare Fig. 1. We point out in this respect that the
 166 sliding threshold θ_M in (15) has been set to the half-way point between the two non-trivial activity levels,
 167 α and 1.

168 It should be noted that the advantage of the compartment model is also reflected in the actual correlation
 169 between proximal and distal input as a measure of successful learning (as done in the previous section), see
 170 Fig. 5 in the appendix. Interestingly, the discrepancies are more pronounced when measuring the correlation
 171 as compared to the accuracy. Moreover, it appears that above-chance accuracy is still present for parameter
 172 values where alignment is almost zero. We attribute this effect to the fact that the classification procedure
 173 predicts the class by choosing the node that has the higher activity, independent of the actual “confidence”
 174 of this prediction, i.e. how strong activities differ relative to their actual activity levels. Therefore, marginal
 175 differences can still yield the correct classification in this isolated setup, but it would be easily disrupted by
 176 finite levels of noise or additional external input.

4 DISCUSSION

177 The workhorse of the brain, pyramidal neurons, possess distinct apical/basal (distant/proximal) dendritic
 178 trees. It is hence likely that models with at least two compartments are necessary for describing the
 179 functionality of pyramidal neurons. For a proposed two-compartment transfer function (Shai et al., 2015b),
 180 we have introduced both unsupervised and supervised learning schemes, showing that the two-compartment
 181 neuron is significantly more robust against distracting components in the proximal input space than a
 182 corresponding (one-compartment) point neuron.

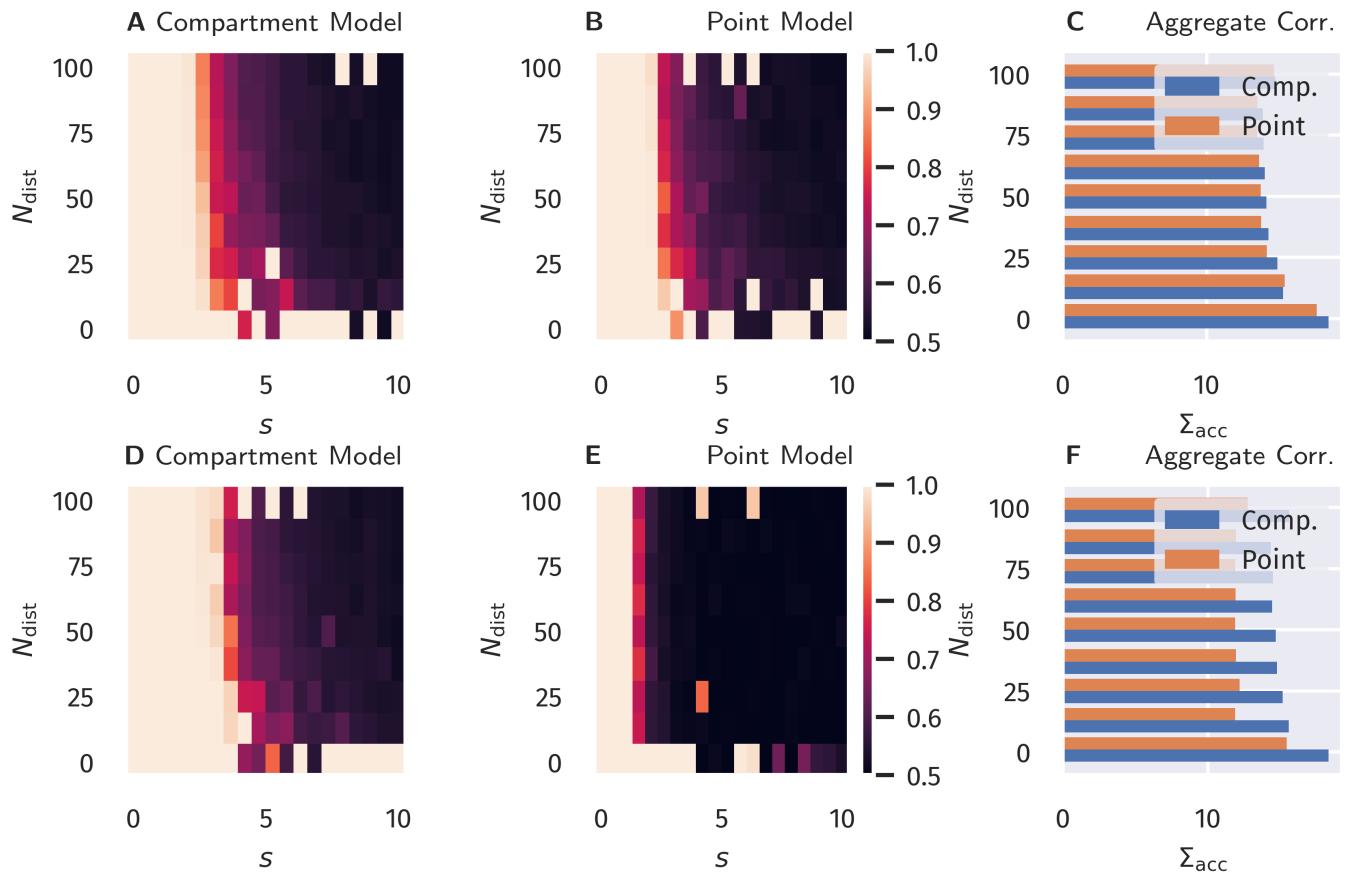

Figure 4. Binary Classification Accuracy. Fraction of correctly classified patterns as illustrated in Fig. 2, see Section 3.2. A–C: Classical Hebbian plasticity. D–F: BCM rule. In the bar plot on the right the sum Σ_{acc} over $s = 0, 0.5, 1.0 \dots$ of the results is given as a function of N_{dist} . Blue bars represents the compartment model, orange the point model.

183 The apical and basal dendritic compartments of pyramidal neurons are located in different cortical layers
 184 Park et al. (2019), receiving top-down and feed-forward signals, respectively. The combined action of these
 185 two compartments is hence the prime candidate for the realization of backpropagation in multi-layered
 186 networks (Bengio, 2014; Lee et al., 2015; Guerguiev et al., 2017).

187 4.1 Learning Targets by Maximizing Correlation

188 In the past, backpropagation algorithms for pyramidal neurons concentrated on learning rules that are
 189 explicitly dependent on an error term, typically the difference between top-down and bottom up signals.
 190 In this work, we considered an alternative approach. We postulate that the correlation between proximal
 191 and distal input constitutes a viable objective function, which is to be maximized in combination with
 192 homeostatic adaptation rules that keeps proximal and distal inputs within desired working regimes. Learning
 193 correlations between distinct synaptic or compartmental inputs is as standard task for Hebbian-type learning,
 194 which implies that the here proposed framework is based not on supervised, but on biologically viable
 195 unsupervised learning schemes.

196 The proximal input current I_p is a linear projection of the proximal input space. Maximizing the
 197 correlation between I_p and I_d (the distal current), can therefore be regarded as a form of canonical
 198 correlation analysis (CCA) (Härdle and Simar, 2007). The idea of using CCA as a possible mode of
 199 synaptic learning has previously been investigated by Haga and Fukai (2018). Interestingly, according to

200 the authors, a BCM-learning term in the plasticity dynamics accounts for a principal component analysis
201 in the input space, while CCA requires an additional multiplicative term between local basal and apical
202 activity. In contrast, our results indicate that such a multiplicative term is not required to drive basal
203 synaptic plasticity towards a maximal alignment between basal and apical input, even in the presence
204 of distracting principal components. Apart from the advantage that this avoids the necessity of giving a
205 biophysical interpretation of such cross-terms, it is also in line with the view that synaptic plasticity should
206 be formulated in terms of local membrane voltage traces (Clopath et al., 2010; Weissenberger et al., 2018).
207 According to this principle, distal compartments should therefore only implicitly affect plasticity in basal
208 synapses, e.g. by facilitating spike initiation.

209 4.2 Generalizability of the Model to Neuroanatomical Variability

210 While some research on cortical circuits suggests the possibility of generic and scalable principles that apply
211 to different cortical regions and their functionality (Douglas and Martin, 2007; George and Hawkins, 2009;
212 Larkum, 2013), it is also well known that the anatomical properties of pyramidal neurons, in particular
213 the dendritic structure, varies significantly across cortical regions (Fuster, 1973; Funahashi et al., 1989).
214 More specifically, going from lower to higher areas of the visual pathway, one can observe a significant
215 increase of spines in the basal dendritic tree (Elston and Rosa, 1997; Elston, 2000), which can be associated
216 to the fact that neurons in higher cortical areas generally encode more complex or even multi-sensory
217 information, requiring the integration of activity from a higher number and potentially more distal neurons
218 (Elston, 2003; Luebke, 2017).

219 With respect to a varying amount of basal synaptic inputs, it is interesting to note that the dimensionality
220 N of the basal input patterns did not have a large effect on the results of our model, see Fig. 3–5, as long as
221 the homeostatic processes provided weight normalization.

222 Apart from variations in the number of spines, variability can also be observed within the dendritic
223 structure itself (Spruston, 2008; Ramaswamy and Markram, 2015). Such differences obviously affect
224 the internal dynamics of the integration of synaptic inputs. Given the phenomenological nature of our
225 neuron model, it is hard to predict how such differences would be reflected, given the diverse dynamical
226 properties that can arise from the dendritic structure (Häusser et al., 2000). The two models tested in
227 our study can be regarded as two extreme cases, where the point neuron represents a completely linear
228 superposition of inputs and the compartment model being strongly nonlinear with respect to proximal
229 and distal inputs. In principle, pyramidal structures could also exhibit properties in between, where the
230 resulting plasticity processes would show a mixture between the classical point neuron behavior (e.g. if a
231 dimensionality reduction of the input via PCA is the main task) and a regime dominated by proximal-distal
232 input correlations if top-down signals should be predicted.

233 4.3 Outlook

234 Here we concentrated on one-dimensional distal inputs. For the case of higher-dimensional distal input
235 patterns, as for structured multi-layered networks, it thus remains to be investigated how target signals are
236 formed. However, as previous works have indicated, random top-down weights are generically sufficient
237 for successful credit assignment and learning tasks (Lillicrap et al., 2016; Guerguiev et al., 2017). We
238 therefore expect that our results can be transferred also to deep network structures, for which plasticity is
239 classically guided by local errors between top-down and bottom-up signals.

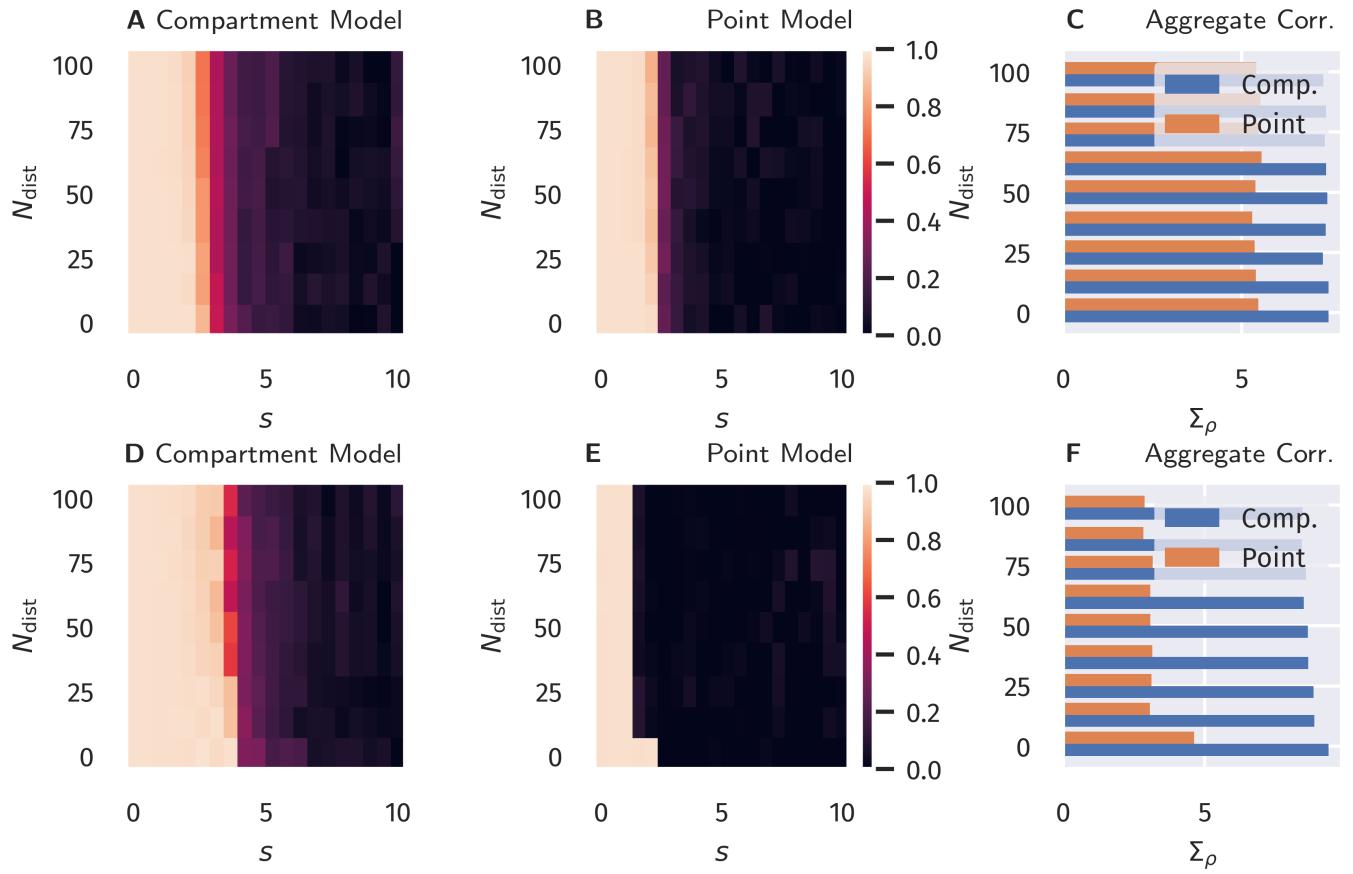

Figure 5. Alignment between Basal and Apical Input after Binary Classification Learning. Correlation between proximal and distal inputs after training, as described in Sect. 3.2. A–C: Classical Hebbian plasticity. D–F: BCM rule. In the bar plot on the right the sum Σ_{acc} over $s = 0, 0.5, 1.0..$ of the results is shown as a function of N_{dist} . Blue bars represents the compartment model, orange the point model.

5 APPENDIX

240 5.1 Alignment in the Classification Task

241 Instead of measuring the model performance in the classification task presented in Sect. 3.2 by the fraction
 242 of correctly classified patterns, as shown in Fig. 4, one can also use the correlation between I_p and I_d , as
 243 done in Sect. 3.1. This is shown in Fig. 5. One observes a more pronounced difference between the point
 244 model and the compartment model, where the latter results in an overall better alignment for the tested
 245 parameter space.

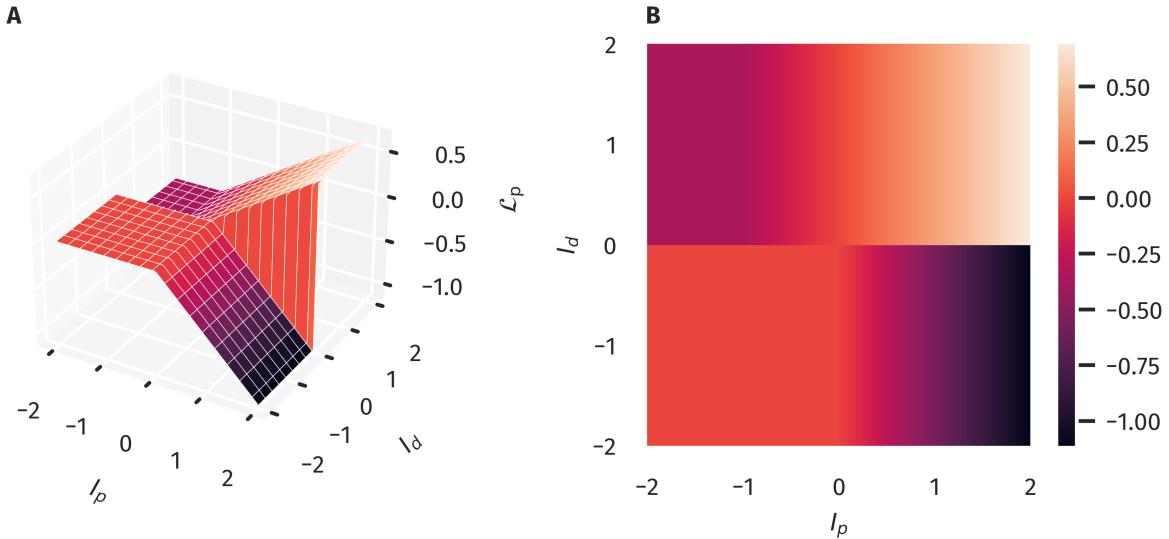

Figure 6. Objective Function for the Proximal Weight Update. The approximate objective function for the proximal weights as given in (21) as a 3d-plot (A) and color-coded (B). This corresponds to a combination of using (1) together with (15). Note the ridge-like structure along the I_p - I_d diagonal, which supports the alignment between proximal and distal input.

246 5.2 Objective Function of BCM Learning in the Compartment Model

247 To gain a better understanding of why the BCM-type learning rule in combination with the implemented
 248 compartment model drives the neuron towards the temporal alignment between I_p and I_d , we can formalize
 249 the learning rule for the proximal weights in terms of an objective function. For this purpose, we further
 250 simplify (1) by replacing the sigmoid functions $\sigma(x)$ by a simple step function $\Theta(x)$. This does not change
 251 the overall shape or topology of the activation in the (I_p, I_d) space but merely makes the smooth transitions
 252 sharp and instantaneous. Using $\Delta w_i \propto y (y - \theta_M) x_i$, we find in this case

$$\Delta w_i \propto \left[(1 - \alpha) \Theta(I_d - \theta_d) \Theta(p - \theta_{p1}) + \alpha(\alpha - 1) \Theta(\theta_d - I_d) \Theta(p - \theta_{p0}) \right] x_i . \quad (20)$$

253 Noting that $\Theta(x)$ is the first derivative of the ReLu function $[x]^+ \equiv \max(0, x)$, we find that this update
 254 rule can be written as

$$\begin{aligned} \Delta w_i &\propto \frac{\partial \mathcal{L}_p}{\partial w_i} \\ \mathcal{L}_p &= (1 - \alpha) \Theta(I_d - \theta_d) [p - \theta_{p1}]^+ + \alpha(\alpha - 1) \Theta(\theta_d - I_d) [p - \theta_{p0}]^+ . \end{aligned} \quad (21)$$

255 The objective function \mathcal{L}_p is shown in Fig. 6. One observes that states closer to the I_p - I_d diagonal are
 256 preferred since they tend to yield higher values of \mathcal{L}_p , while the opposite is the case for off-diagonal states.

257 It should be noted, though, that the objective function is not scale-invariant (as would be e.g. if the
 258 squared error was used) in the sense that the prior distributions of both proximal and distal inputs need
 259 a certain mean and variance to cover a region of input states for which the described effects can take
 260 place. As a counterexample, one could imagine that the input samples only covered a flat area of \mathcal{L}_p , as
 261 for example in Fig. 6B in the lower left quadrant, leading to a zero average gradient. This is prevented,
 262 however, by the homeostatic processes acting simultaneously on the gains and biases, making sure that
 263 the marginal distributions of I_p and I_d are such that higher correlations are preferred. For example, if we

264 assume a Gaussian marginal distribution for both I_p and I_d with zero means and a standard deviation of 0.5
265 (which is used as a homeostatic target in the simulations), the expected value of $\mathcal{L}(I_p, I_d)$ is -0.055 if I_p
266 and I_d are completely uncorrelated, and 0.07 in the perfectly correlated case.

CONFLICT OF INTEREST STATEMENT

267 The authors declare that the research was conducted in the absence of any commercial or financial
268 relationships that could be construed as a potential conflict of interest.

AUTHOR CONTRIBUTIONS

269 Both authors, F.S. and C.G., contributed equally to the writing and review of the manuscript. F.S. provided
270 the code, ran the simulations and prepared the figures.

ACKNOWLEDGMENTS

271 The authors acknowledge the financial support of the German research foundation (DFG)

DATA AVAILABILITY STATEMENT

272 The simulation datasets for this study can be found under <https://cloud.itp.uni-frankfurt.de/s/mSRJ6BPXjwwHmfq>. The simulation and plotting code for this project can be found under
273 https://github.com/FabianSchubert/frontiers_dendritic_coincidence_detection.
